# 1 Introduction

# 2 Generalized Linear Models

# 3 Nonlinear Terms

The gnm package provides a flexible framework for the specification and estimation of generalized models with nonlinear terms. Multiplicative interaction terms can be estimated using the in-built capability of the gnm function and are specified in the model formula using the symbolic function Mult. Other nonlinear terms can be estimated using plug-in functions for gnm and are specified using Nonlin.

There are two plug-in functions currently available in the gnm package: MultHomog for fitting multiplicative interaction terms with homogeneous effects and Dref for fitting diagonal reference terms. Users may also define custom plug-in functions to fit other types of nonlinear terms.

### 3.1 Multiplicative Interaction Terms using Mult

Multiplicative interaction terms can be included in the formula argument to gnm by using the symbolic wrapper function Mult. Factors in the interaction are passed as unspecified arguments to Mult and are expressed by symbolic linear formulae. An intercept is automatically added to each factor unless otherwise specified. For example, to fit the row-column association model

$$\log \mu_{rc} = \alpha_r + \beta_c + \gamma_r \delta_c,$$

also known as the Goodman RC model [1], the formula argument of gnm would be

mu 
$$\sim$$
 R + C + Mult(-1 + R, -1 + C)

where R and C are row and column factors respectively.

Mult has one specified argument multiplicity, which is 1 by default. This argument determines the number of multiplicative components that are fitted. For example,

mu 
$$\sim$$
 R + C + Mult(-1 + R, -1 + C, multiplicity = 2)

would give the RC(2) model [1]

$$\log \mu_{rc} = \alpha_r + \beta_c + \gamma_r \delta_c + \theta_r \phi_c.$$

In some contexts, it may be desirable to constrain one or more of the multiplicative factors so that the factor is always nonnegative. This may be achieved by defining the factor as an exponential, as in the following 'uniform difference' model [2?]

$$\log \mu_{ijt} = \alpha_{it} + \beta_{jt} + e^{\gamma_t} \delta_{ij}.$$

Exponentiated factors can be specified in gnm models using the symbolic function Exp, for example the uniform difference model above would be specified by the formula

mu 
$$\sim$$
 R:T + C:T + Mult(Exp(-1 + T), R:C, multiplicity = 2)

#### 3.2 Other Nonlinear Terms using Nonlin

Nonlinear terms which can not be specified using Mult may be specified using Nonlin. This symbolic function indicates a term which requires a plug-in function to estimate the associated parameters. There are two arguments to Nonlin: a call to the relevant plug-in function and if necessary, a data frame containing any variables that are required by specified arguments of the plug-in function, which do not appear in any unspecified arguments of the plug-in function or elsewhere in the model formula.

For example, in the formula

Nonlin is used to specify a term that requires the plug-in function PlugInFunction. As the factor C only appears in the specified arguments of the call to PlugInFunction, a data frame containing factor C has been passed to the data argument of Nonlin. Note that this would not be necessary if C could be found in an environment on the search path (given by search()).

The two plug-in functions included in the gnm package are described below, followed by a guide to writing custom plug-in functions.

#### 3.2.1 MultHomog

The MultHomog function provides the tools required to fit multiplicative interaction terms in which the level effects are constrained to be equal across the factors. The arguments of MultHomog are the factors in the interaction, which are assumed to be objects of class "factor". Like a Mult term, the interaction can include any number of factors, but there is no multiplicity argument.

As an example, consider the following association model with homogeneous row-column effects

$$\log \mu_{rc} = \alpha_r + \beta_c + \theta_{rc} + \gamma_r \gamma_c.$$

To fit this model, the formula argument to gnm would be

If the factors passed to MultHomog do not have exactly the same levels, a common set of levels is obtained by taking the union of the levels of each factor, sorted into increasing order.

#### 3.2.2 Dref

Dref is a plug-in function to fit diagonal reference terms involving two or more factors with a common set of levels. A diagonal reference term comprises an additive component for each factor. For a given data point, the component for the i'th factor, say F, is

$$w_i \gamma_f$$

where  $w_i$  is the weight for factor i,  $\gamma_f$  is the "diagonal effect" for level f and f is the level of F for the given data point.

The weights are constrained to be nonnegative and to sum to one so that a "diagonal effect", say  $\gamma_l$ , is the value of the diagonal reference term for data points with level l across the factors. Dref constrains the weights by defining them as

$$w_i = \frac{e^{\delta_i}}{\sum_{r}^{n} e^{\delta_r}}$$

and estimating the  $\delta_i$ .

Factors in the interaction are passed to unspecified arguments of  $\mathsf{Dref}$ . For example, the following diagonal reference model for a contingency table classified by the row factor R and the column factor C

$$\mu_{rc} = \frac{e^{\delta_1}}{e^{\delta_1} + e^{\delta_2}} \gamma_r + \frac{e^{\delta_2}}{e^{\delta_1} + e^{\delta_2}} \gamma_c,$$

would be specified by the formula

```
mu \sim -1 + Nonlin(Dref(R, C))
```

Dref has one specified argument formula, which is a symbolic description of the dependence of  $\delta_i$  on any covariates. For example, the formula

```
mu \sim -1 + x + Nonlin(Dref(R, C, formula = ~1 + x))
```

specifies the following diagonal reference model

$$\mu_{rc} = \beta_X x + \frac{e^{\xi_1 + \beta_1 x}}{e^{\xi_1 + \beta_1 x} + e^{\xi_2 + \beta_2 x}} \gamma_r + \frac{e^{\xi_2 + \beta_2 x}}{e^{\xi_1 + \beta_x} + e^{\xi_2 + \beta_2 x}} \gamma_c,$$

The default value of formula is  $\sim 1$ , so that constant weights are estimated. The coefficients returned by gnm are those that are directly estimated, i.e. the  $\delta_i$  or the  $\xi_i$  and  $\beta_i$ , rather than the implied weights  $w_i$ .

#### 3.2.3 Custom Plug-in Functions

Custom plug-in functions may be written to enable gnm to fit nonlinear terms that can not be specified by Mult or the plug-in functions provided by the gnm package.

There are no constraints on the arguments that a plug-in function may have. However it should not be assumed that model variables exist in an environment on the search path, since gnm does not assume this. Rather the function getModelFrame should be used to get the model.frame used by gnm, which will have all the model variables and also attributes useful for model.matrix etc.

For example, the first few lines of the MultHomog function are

```
MultHomog <- function(...){
  labelList <- as.character((match.call(expand.dots = FALSE))[[2]])
  gnmData <- getModelFrame()
  designList <- lapply(gnmData[, labelList], class.ind)</pre>
```

The names of the factors in the interaction are assigned to labelList, and the model.frame used by gnm is assigned to gnmData. The factors can then be accessed by name from gnmData, as in the call to lapply.

The plug-in function should return a list with the following components

start (optional) either a vector of default starting values for the parameters or a function which takes the number of parameters and returns a vector of default starting values. See Section 4.2 for details of how these values will be used if provided and the generic default values that will be used otherwise.

labels a character vector of labels for the parameters (to which gnm will prefix the call to the plug-in function).

**predictor** a function which takes a vector of parameter estimates and returns either a vector of fitted values or a matrix whose columns are additive components of the fitted values.

**localDesignFunction** a function which takes the specified arguments coef (a vector of parameter estimates) and predictor (the result of the predictor function), and returns the local design matrix.

As an example of a start component, Dref simply returns

```
rep(0.5, length(labels))
```

where labels is the vector of parameter labels to be returned as the labels component, for instance

```
c("A", "B", "1", "2", "3", "4", "5", "6", "7")
The MultHomog function provides a simple example of a predictor component:
predictor <- function(coef) {
    do.call("pprod", lapply(designList, "%*%", coef))
}</pre>
```

which computes the product of the vectors found by multiplying the design matrix for each factor in the interaction (held in designList) by the homogeneous coefficients (in coef). This function takes advantage of *lexical scoping*: designList is an object defined in MultHomog, which predictor is able to find because predictor is also defined in MultHomog and hence MultHomog is the enclosing environment of predictor.

The localDesignFunction created by MultHomog is slightly more complicated:

This function only requires the argument coef, but since the local design function returned by a plug-in function must also take the argument predictor, further arguments are allowed by the use of the special argument "...".

# 4 Controlling the Fitting Procedure

gnm has a number of arguments which affect the way a model will be fitted. Basic control parameters and starting values can be set by control and start respectively. Parameters can be constrained to zero by specifying a constrain argument. Finally parameters of a stratification factor can be handled more efficiently by specifying the term in an eliminate argument. These options are described in more detail below.

## 4.1 Using control with gnmControl

The control argument provides a way to specify the tolerance level for convergence, the number of starting iterations and the maximum number of main iterations, as well as the option to trace the deviance throughout the fitting process. By default, the control argument is a call to gnmControl using any arguments passed on from gnm. gnmControl creates a list of the control parameters, including any at their default values. For example

```
gnm(mu \sim R + C + Mult(-1 + R, -1 + C), tolerance = 1e-6, iterStart = 3) is equivalent to gnm(mu \sim R + C + Mult(-1 + R, -1 + C), control = gnmControl(tolerance = 1e-6, iterStart = 3))
```

which is the same as

```
gnm(mu \sim R + C + Mult(-1 + R, -1 + C),
control = list(tolerance = 1e-6, iterStart = 3, iterMax = 500, trace = FALSE))
```

## 4.2 Using start

In some contexts, the default starting values may not be appropriate and the algorithm will fail to converge, or perhaps only converge after a large number of iterations. Alternative starting values may be passed on to gnm by specifying a start argument. This should be a numeric vector of length equal to the number of parameters (or possibly the non-eliminated parameters, see Section 4.4), however missing starting values (NAs) are allowed.

If there is no user-specified starting value for a parameter, the default value is used. This feature is particularly useful when adding terms to a model, since the estimates from the original model can be used as starting values, as in the example below

```
\label{eq:model1} $$ \mbox{model1} <-\ gnm(mu \sim R + C + Mult(-1 + R, -1 + C))$$ $$ model2 <-\ gnm(mu \sim R + C + Mult(-1 + R, -1 + C, multiplicity = 2), $$ start = c(coef(model1), rep(NA, 10))$$
```

gnm can be run with method = "coef" to identify the parameters of a model prior to
estimation, to assist with the specification of arguments such as start.

The starting procedure used by gnm is as follows

1. Generate starting values  $\theta_i$  for all parameters i = 1, ..., p from the Uniform(-0.1, 0.1) distribution. Shift these values away from zero as follows

$$\theta_i = \begin{cases} \theta_i - 0.1 & \text{if } \theta < 1\\ \theta_i + 0.1 & \text{otherwise} \end{cases}$$

- 2. Replace generic starting values with any starting values specified by plug-in functions.
- 3. Replace default starting values with any starting values specified by the start argument of gnm.
- 4. Compute the glm estimate of any parameters in linear terms that were not specified by start, offsetting the contribution to the predictor of any parameters specified by start or a plug-in function.
- 5. Run starting iterations: update any parameters in nonlinear terms that were not specified by **start** or a plug-in function one at a time, updating *all* linear terms after each round of nonlinear updates.

Note that no starting iterations will be run if all parameters are specified by the start argument of gnm.
